

# Resource allocation strategies behind rate-yield phenotypes in *E. coli*

V. Baldazzi, D. Ropers, J-L. Gouzé, T. Gedeon,  
H. de Jong

*eLife* 12:e79815 (2023)

### Bacterial growth involves

- the conversion of nutrients to biomass
- energy stored in nutrients transferred to energy cofactors (ATP) driving the biomass synthesis
- coupled energy and mass fluxes

## Bacterial growth involves

- the conversion of nutrients to biomass
- energy stored in nutrients transferred to energy cofactors (ATP) driving the biomass synthesis
- coupled energy and mass fluxes

Two macroscopic criteria characterize microbial growth:

- **growth rate** *i.e.* the speed of conversion of nutrients into biomass
- **growth yield** *i.e.* the efficiency of the process

$$\frac{\text{Biomass produced}}{\text{Nutrient consumed}}$$

Bacterial growth has been analyzed from the perspective of proteome allocation:

- Proteins are main component of biomass
- Proteins catalyze reactions necessary for growth
- Proteome composition reflects **resource allocation strategy**

Relation between resource allocation and rate and yield.

- Linear relation between **growth rate** and ribosomal protein fraction

Scott et al. (2010)

## Overflow metabolism:

*Molenaar et al. (2009); Basan et al. (2015)*

- Switch from high-yield respiration to a low-yield fermentation for high growth rates
- Trade-off between ATP yield and investment in enzyme synthesis
  - > Gain in proteome efficiency through fermentation

## Overflow metabolism:

*Molenaar et al. (2009); Basan et al. (2015)*

- Switch from high-yield respiration to a low-yield fermentation for high growth rates
- Trade-off between ATP yield and investment in enzyme synthesis
  - > Gain in proteome efficiency through fermentation

## Phenotypic variability in bacterial growth

In same conditions, different *E. coli* strains show large variations in growth rate and yield

A 7 *Escherichia coli* strains commonly used in industrial processes:

Monk et al. (2016)

- What is the range of rate-yield phenotypes predicted by changes in proteome composition?
- Does the predicted range correspond to observed rate-yield variability?

### Approach

Develop a coarse-grained model of **coupled energy and mass fluxes** in microorganisms, based on minimal assumptions

*Baldazzi et al. (2023)*

## Model definition

- Macroscopic reactions for carbon uptake and metabolism, biomass synthesis, ATP production
- Biomass  $B = \beta$  (Proteins + Other macromolecules + Metabolites)
- 5 allocation parameters  $\chi_u, \chi_r, \chi_c, \chi_{er}, \chi_{ef}$  define the resource allocation strategy of the cell ( $\sum_i \chi_i = 1$ )

Carbon balance:

$$\frac{dc}{dt} = v_{mc} - v_{mer} - \rho_{mef} v_{mef} - \rho_{ru} (v_r + v_{mu}) - (\mu + \gamma) c,$$

$$\frac{du}{dt} = v_{mu} - (\mu + \gamma) u,$$

$$\frac{dr}{dt} = \chi_r v_r - (\mu + \gamma) r,$$

$$\frac{dm_u}{dt} = \chi_u v_r - (\mu + \gamma) m_u,$$

$$\frac{dm_c}{dt} = \chi_c v_r - (\mu + \gamma) m_c,$$

$$\frac{dm_{er}}{dt} = \chi_{er} v_r - (\mu + \gamma) m_{er},$$

$$\frac{dm_{ef}}{dt} = \chi_{ef} v_r - (\mu + \gamma) m_{ef}.$$

Energy balance:

$$\frac{da^*}{dt} = n_{mer} v_{mer} + n_{mef} v_{mef} - n_r v_r - n_{mu} v_{mu} - v_d$$

### Total biomass concentration

- $1/\beta = (m_c + m_{er} + m_{ef} + r + m_u + u + c)$

## Assumptions

### Total biomass concentration

- $1/\beta = (m_c + m_{er} + m_{ef} + r + m_u + u + c)$

### Total concentration of energy co-factors

- $a + a^* = a_0$  by some undefined mechanisms

### Total biomass concentration

- $1/\beta = (m_c + m_{er} + m_{ef} + r + m_u + u + c)$

### Total concentration of energy co-factors

- $a + a^* = a_0$  by some undefined mechanisms

### Rates

- Michaelis-Menten kinetics to define the reaction rates

$$v_r(r, c, a^*) = r k_r \frac{c}{c + K_r} \frac{a^*}{a^* + K_{ar}},$$

- Constant external substrate concentration  $S$

$$v_{mc}(m_c) = m_c k_{mc} \frac{S}{S + K_S} = m_c e_s$$

## Model calibration

We used different datasets for *E.coli* BW2115 on minimal medium:

- Metabolite concentrations from Bennet et al. (2009), Gerosa et al. (2015)
  - Protein concentrations from Schmidt et al. 2016
  - Metabolic fluxes from van Rijsewijk and al. (2011), Gerosa et al. (2015)
1. Use literature information to estimate the total biomass density, the total protein and metabolites concentrations
  2. Use proteomics and metabolomics data to estimate the concentrations of the different constituents distinguished in the model, based on **proportions**
  3. Derive rate parameters using the fluxes and concentrations

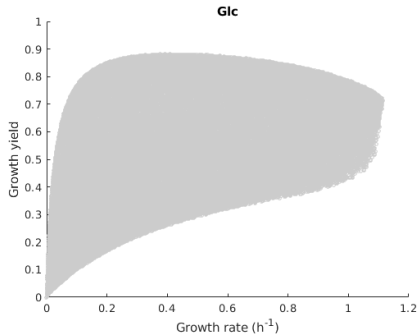

Different carbon sources: glucose, glycerol  
Different culture conditions: batch, chemostat

1. **Random sampling** of  $(\chi_u, \chi_r, \chi_c, \chi_{er}, \chi_{ef})$  values
2. Numerical simulation and steady-state computation (variables, fluxes)
3. Plot of steady-state growth rate ( $\mu$ ) vs yield ( $Y$ ):

$$\mu = \frac{1}{B} \frac{dB}{dt}$$

$$Y = \frac{1}{\beta} \frac{\mu}{v_{mc}}$$

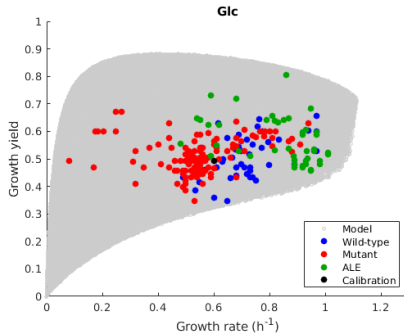

- No optimisation!
- Fixed environment

- Maximum yield increase at low growth rates: lower burden of the non-growth-associated maintenance costs
- Trade-off between rate and maximum yield at higher growth rates

# Predicted vs observed rate-yield phenotypes

- Maximum yield increase at low growth rates: lower burden of the non-growth-associated maintenance costs
- Trade-off between rate and maximum yield at higher growth rates
- Very good agreement with data from different *E. coli* strains

## Predicted vs observed fluxes

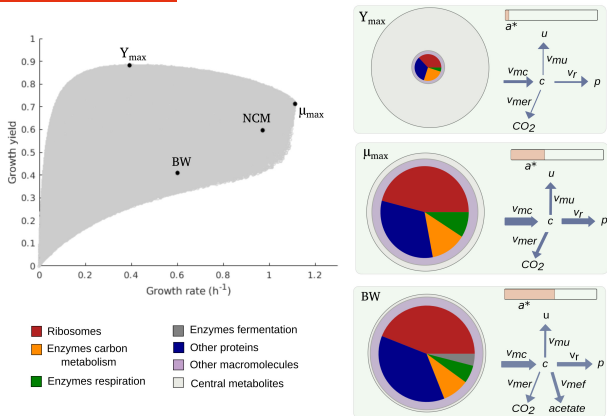

- Correlation between growth rate and glucose uptake
- Additional trade-off between maximum growth yield and glucose uptake (*Cheng et al. (2019)*)

## Predicted vs observed fluxes

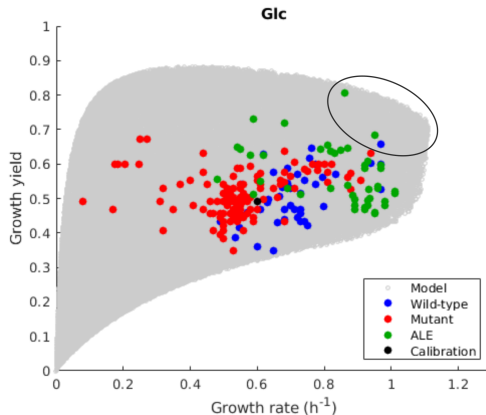

- Trade-off between acetate secretion rate and growth yield
  - > maximum growth yield requires respiration
- No relation between growth rate and acetate secretion rate
  - > high growth rates are possible for a wide range of ATP production modes
- Existence of wild-type and ALE (Artificial Lab Evolution) strains with high growth rate and no fermentation

## Opening the black box...

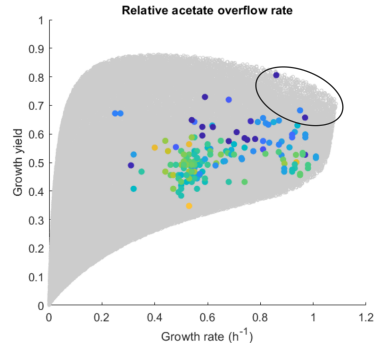

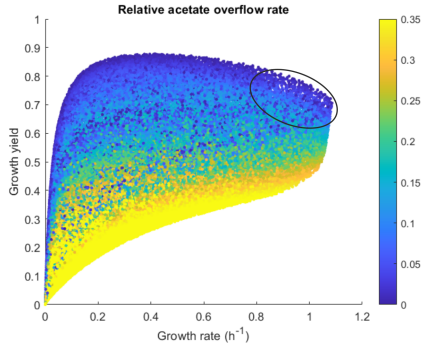

- Model allows to connect rate-yield phenotypes to the underlying resource allocation strategies
- Tight and complex relation between resource allocation, biomass composition and fluxes

Focus on a specific rate-yield phenotype: **high rate and high yield**

Focus on a specific rate-yield phenotype: **high rate and high yield**

### Accepted view

- Fast growth needs a larger ribosomal fraction
- Switch from respiration to fermentation allows to *free* proteome resources for growth
  - > Fermentation requires less protein than respiration

⇒ Overflow metabolism is required for fast growth

*Basan et al. (2015)*

### Accepted view

- Fast growth needs a larger ribosomal fraction
- Switch from respiration to fermentation allows to *free* proteome resources for growth
  - > Fermentation requires less protein than respiration

⇒ Overflow metabolism is required for fast growth

*Basan et al. (2015)*

Which resource allocation strategies can lead to **fast and efficient** growth?

Fast and efficient growth rate is supported by:

- increased nutrient uptake
- increased protein synthesis

but...

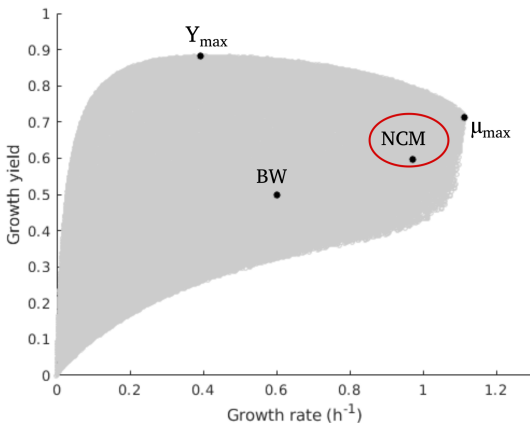

- total protein (ribosome) concentration is lower
- ATP concentration is reduced

⇒ Increased **enzyme saturation** thanks to increased **metabolite concentration**

$$v_r = k_r r \frac{c}{c + K_r} \frac{a^*}{a^* + K_{ar}}$$

How these results compare to known observations?

How these results compare to known observations?

NCM vs BW phenotype:

- Increased uptake rate  $v_{mc}$
- Increased metabolite fraction

How these results compare to known observations?

## NCM vs BW phenotype:

- Increased uptake rate  $v_{mc}$
- Increased metabolite fraction

Our model reduces to the one of Basan *et al.* when assuming

- The concentrations of metabolites, ATP and other macromolecules are **constant**
- Biomass = Total proteins mass

Under these hypotheses:

$$v_r = k_r r \frac{c}{c + K_r} \frac{a^*}{a^* + K_{ar}} = k'_r r,$$

$$v_{mer} = k'_{mer} m_{er},$$

$$v_{mef} = k'_{mef} m_{ef} \dots$$

The trade-off between enzymes and metabolites is no longer possible!

- Coarse-grained model of coupled mass and energy fluxes based on minimal assumptions
- Model can reproduce the observed variability in *E. coli* rate-yield phenotypes
  - > resource (protein) allocation strategy as a major determinant

Model helps to better understand cell functioning and capabilities:

- Common lab *E.coli* strains are not optimal for growth on a single substrate
- Fermentation is not required for high growth rates
  - > some evolved strains only use respiration
- Strategies for fast and efficient growth can be achieved by enzyme saturation
  - > importance to account for metabolites in biomass composition

### From the experimental side:

- Better characterize interesting ALE strains
- Explore the (low-rate)-high yield zone
- Apply to other organisms

### From the theoretical side:

- Mathematical analysis of rate-yield trade-off (Pareto front)
- Dynamics of resource allocation
  - > regulatory function for  $\chi$ s as a function of concentrations
  - > explanation of strain evolution towards fast and efficient growth

Open PhD position at Inria-INRAE

**Multi-omics data integration for the analysis of microbial community dynamics in plant leaves**

collab. Simon Labarthe (Inria Bordeaux, France)

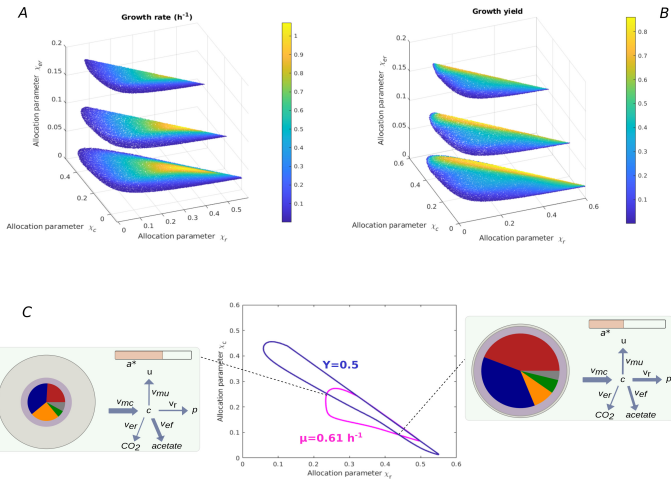

Thank you for your attention!

Any questions?

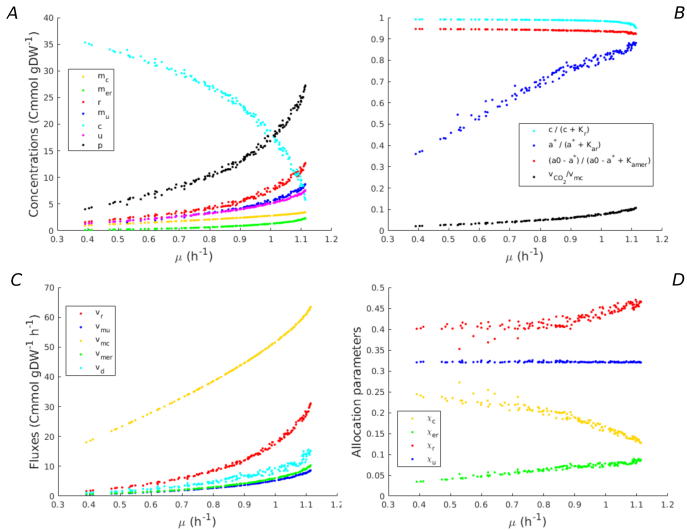

$$\begin{aligned}\mu &= \frac{1}{B} \frac{dB}{dt} = \beta \frac{1}{B} \frac{d(M_u + R + M_c + M_{er} + M_{ef} + C + U)}{dt} \\ &= \beta (v_{mc} - v_{mer} - \rho_{mef} v_{mef} - (\rho_{ru} - 1)(v_r + v_{mu})) - \gamma\end{aligned}$$

$$Y = \frac{1}{\beta} \frac{\mu}{v_{mc}} = \frac{v_{mc} - v_{mer} - \rho_{mef} v_{mef} - (\rho_{ru} - 1)(v_r + v_{mu}) - \gamma/\beta}{v_{mc}}$$

# Pareto front

ATP yield coefficients set from literature data

ATP cost for biomass synthesis: theoretical values from literature + correction for energy spilling

Affinity Constants following Bennet et al. (2009) we assumed that

- reactions involved in central carbon metabolism approximately work in the linear regime i.e. Michaelis-Menten constant close to substrate concentration ( $K_m$  values from Dourado et al. (2001))
- reactions involving ATP/NAD<sup>+</sup> cofactors are saturated ( $K_m \gg$  ATP/NAD<sup>+</sup> concentrations)
- reactions involving ADP/NADH work in a linear regime, with  $K_m$  values close to their cofactor value

## Comparison to Basan model

Our model can be simplified to the one of Basan's using the following assumptions:

1. Assume that concentration of carbon metabolites and other macromolecules are constant and negligible with respect to proteins
  - > Biomass  $\approx$  Proteins
  - > Linear rates  $v = kE$
2. Neglect energy dissipation  $v_d$
3.  $(\mu + \gamma) c$  small

At high  $\mu$  the fraction of fermentation protein increases thanks to their lower protein cost ( $n_{mef}k_{mef} > n_{mer}k_{mer}$ ).

The relation between growth and yield is complex:

- A **positive relation** has been observed in nutrient-limited aquatic ecosystems *Smith & Praie (2004)*

The relation between growth and yield is complex:

- A **positive relation** has been observed in nutrient-limited aquatic ecosystems *Smith & Praie (2004)*
- A **trade-off** has been observed in natural and laboratory communities *Lipson (2009), Novak et al. (2006)*

## At the reaction level:

### Thermodynamic trade-off

- Rate is proportional to  $\Delta G$
- Maximal yield for  $\Delta G = 0$

McLean (2008)

## At the system level

- ATP-producing pathways with different ATP yield
- catabolism-anabolism imbalance
  - > energy-spilling reactions

## Model predictions for NCM-like phenotype

- Look for resources allocation strategies giving the expected  $(\mu, Y, v_{mc}, v_{mef})$  for NCM strain
- Comparison to NCM proteomic data
  1. constant metabolic rates
  2. variable metabolic rates :  $k_{mc}, k_{mer}, k_{mef}$

## NCM3722
