*Synthesis: Equatorial Ionospheric Morphology at Large
and Small Scales*

M. A. Abdu
(Instituto Nacional de Pesquisas Espaciais, São José dos Campos, Brazil)

Synthesis: Equatorial ionospheric morphology at large and small scales (Abdu)

The ionosphere -thermosphere -atmosphere coupling, involving the wind system, dynamo electric field, and plasma fountain are the major factors that determine the equatorial ionosphere phenomena and their morphology at large and small scales. A schematic representation of the coupling processes that form the basis of the phenomenology is shown in **Fig.1**.

The dynamo electric field generated by the tidal wind system at E layer heights (a) establishes the quiet time ionospheric current system, and (b) being mapped on to the equatorial F layer heights produces the plasma fountain that controls the plasma density distribution of the tropical ionosphere. The electric field produced by the F layer dynamo becomes dominant only after sunset when the E layer electron density, and therefore the conductivity, decays due to recombination. While the electric fields, driven by the wind system are the immediate driving forces for the major phenomena during day and night, the wind system that produce these electric field, act in a more direct way also to control the morphology of these phenomena.

The major equatorial phenomena are: 1- the electrojet current systems and associated plasma structures, 2- ionization anomaly and associated anomalies in the neutral temperature and wind; 3- spread $-F$ /plasma bubbles structures of the nighttime ionosphere.

The local time dependence of the major phenomena that result from the coupling processes is shown in **Fig.2**.

The equatorial electric fields and their temporal variations serve as the immediate cause of the spatial and temporal variations in the phenomenology, and the morphology of the equatorial ionosphere-thermosphere system. The equatorial electric field pattern for different season as obtained from Jicamarca radar observations is shown in **Fig 3**. An empirical model of the electric field for different longitude sectors of the globe, based on the AE-E satellite data and Jicamarca radar observations, are presented in **Fig. 4**.

Morphology at large scale:

Daytime electric field, which is eastward, produces, under the $E \times B$ force, upward plasma drift constituting the daytime plasma fountain. An example of the low latitude plasma drift pattern resulting from the combined action of an upward $E \times B$ drift near the equator and a downward diffusion along the magnetic field lines resulting from a numerical model calculation is shown in **Fig.5**.

This fountain is responsible for the formation of the ionization peaks in the subtropics on both sides of anomaly. An example of a simulation using a numerical computer code showing the low latitude ionization crests symmetrically formed on either side of an equatorial trough is shown in **Fig. 6**.

An example of latitudinal distribution of NmF2 /TEC as a function of local time modeled for different values of equatorial electric field is shown in **Fig. 7**. Larger electric field produces more intense and broader ionization anomaly. Observational evidence showing the control of equatorial electric field on the formation of the equatorial anomaly is presented in **Fig 8**.

Plasma drift pattern as a result of combined actions including the effect of a trans-equatorial meridional wind resulting from simulation by the Sheffield University Plasmasphere-ionosphere model (SUPIM) is shown in **Fig. 9** for conditions representative of three longitude sectors, Fortaleza Brazil, Jicamarca (Peru) and Thumba (India). A trans-equatorial wind can cause asymmetric formation of the anomaly peaks, with the height of the F2 layer being lower (higher) on the down wind (upwind) hemisphere, as the example of a model calculation presented in **Fig. 10**.

The ionospheric morphology determined by these electrodynamic processes can go through large variations with longitude, due to the longitudinal variation in the geomagnetic field configuration over the low latitude region as shown in the global maps of the magnetic field intensity and declination angle of **Fig.11**.

Especially, the magnetic anomaly characterized by a global minimum of intensity, in the South Atlantic and Brazil, and the associated large magnetic declination angle, produce important deviation in the ionospheric morphology of this longitude sector as compared to other longitude sectors, some aspects of which also will be considered here.

An example of the equatorial anomaly pattern in electron density as observed from ground based and satellite born topside sounders are shown in **Figs.12 a, b, and c**. Some additional morphological features of NmF2, hmF2 and TEC over low latitude are shown in **Figures 13**.

A recent phenomenon of the equatorial F layer being investigated concerns the formation of an additional layer above the F2 peak, known as the F3 layer. The F3 layer has been observed at locations close to the dip equator during daytime more frequently around pre noon hours. The layer was first observed over Fortaleza in Brazil. The mechanism of its formation has been investigated with the help of the Sheffield University Plasmasphere-Ionosphere Model (SUPIM) by Balan et al. (1999). Its occurrence pattern on a long-term basis has been studied by Batista et al. (2001). Some results are presented in **Figs. 14, 15 and 16**.

Equatorial anomaly has been observed also in thermospheric zonal wind and temperature by Dynamic Explorer satellite that is associated with the ionization anomaly. An example is shown in **Fig.17**.

Morphology at small scale.

Equatorial spread F

As compared to the temporal and spatial scales of the morphological features described above, the equatorial spread F structures have morphological features at much smaller scales, although the plasma bubble structures that envelop spread F irregularities have scale sizes of 100s of kilometers perpendicular to field line and thousands of kilometer extension along the field line.

The equatorial F layer height increases in the evening hours under the action of an enhanced zonal (eastward) electric field, known as prereversal enhancement electric field. This feature representing low and high solar activity conditions is shown in **Fig.18**. Such layer uplift is a prerequisite for the occurrence of spread F irregularities that may last for several following hours of the night.

The local time distribution of Spread F, as observed in ionograms, is presented in **Fig.19**. It is plotted in the form of its monthly mean percentage occurrence representing low and high solar activity years. These results are for the equatorial station Fortaleza and the anomaly crest (low latitude) location Cachoeira Paulista in Brazil. The post sunset ESF onset, rapid increase in the occurrence rate during the first 1-2 hours attaining peak activity around ~22 LT and the gradual decay towards morning hours, and the seasonal variation in these patterns are evident in this figure.

Latitudinal distribution of spread F occurrence as obtained from topside sounder data shows that the irregularity belt is confined to $\pm 20^\circ$ in latitude as presented in **Fig.20**. A representation of the global statistical distribution of scintillation occurrence is presented in **Fig 21**, which shows the pattern of local time-latitude extension of the scintillation producing structures.

The seasonal variation of spread F irregularity occurrence is longitude dependent. Over Brazil the season of maximum occurrence is centered around December solstice as was evident in **Fig.19**. However, over Jicamarca/Huancayo, Peru which is $\sim 30^\circ$ west of the Brazilian stations the spread F occurrence presents mostly equinoctial maximums. Such features are shown for the cases of ionogram spread F and UHF scintillation in **Figs. 22 and 23** respectively.

Such differences in the seasonal pattern of spread F occurrence are associated with the difference magnetic declination angle that characterize these longitude sectors as was pointed out with reference to **Fig.11**. It is known that a first order requirement for the initiation of spread F is the large prereversal enhancement electric field that causes the uplift of the F layer in the post sunset hours. The amplitude of the prereversal enhancement attains a maximum when the solar terminator becomes aligned with magnetic meridian whereby near simultaneous sunset occurs at conjugate E layers, a condition that is fulfilled in December solstice over Brazil (due to the large westward declination angle, $\sim 22^\circ$ W in this sector), and during equinoctial months over Peru (where the declination angle is small, $\sim 4^\circ$ E). The seasonal variation of scintillation occurrence

pattern for different longitude sectors of the globe is presented in **Fig. 24** which seems to confirm the magnetic declination control of the seasonal pattern in the irregularity, suggested from the comparison spread F data from Brazil and Peru.

The spread F occurrence depends positively on the solar UV radiation represented by the F10.7 flux. Such dependence arises because the prereversal electric field enhancement amplitude also increases with increase of solar flux as shown in **Fig.25**. A statistical dependence of spread F occurrence on F10.7 is presented in **Fig.26**. **(The figures 25 and 26 are not included here)**
